***Abstract*—Accurate traffic forecasting is an essential part of the development of intelligent transportation systems and the intelligent management of traffic flow. The traditional traffic forecasting approaches depend on either static or minimally dynamic graphs, which cannot capture the variations of the spatial-temporal relationship well. The proposed TAGM-STGCN model considers dynamic graph processing, temporal graph memory, and regime-aware modulation to capture the current traffic pattern, thus addressing the problem well. Dynamic Adjacency Module predicts the changes in the spatial-temporal relationship among the traffic points. The Temporal Graph Memory Module uses the historical location information to make the dynamic graph more stable. Finally, the Regime Encoder Module dynamically updates the adjacency matrix according to the current traffic state. The experiments using PeMS-D7 and PeMS-BAY validate that the proposed model performs better in traffic speed forecasting.**

***Index Terms*—traffic forecasting, spatio-temporal graph convolutional networks, dynamic graph learning, temporal graph memory, regime-aware modulation.**

I. Introduction

Traffic forecasting is a key part of developing intelligent transportation systems (ITS) applications. ITS allows for the creation of various applications, such as traffic congestion management and route optimization. The rise of traffic sensors and monitoring systems makes it easier to continuously gather traffic data. Still, predicting traffic conditions remains difficult because of the spatial and temporal relationships within traffic systems [1]. Traffic generation comes from two sources: (i) looking at historical data and the current situation of nearby road segments, and (ii) unplanned traffic jams and shifts in national traffic patterns.

The Spatio-Temporal Graph Convolutional Network (STGCN) model has received significant attention as a novel approach to traffic prediction by combining the benefits of graph convolution and temporal convolution to learn spatial locations and temporal evolution [2]. The conventional STGCN model is quite effe ctive in accurately forecasting traffic conditions. However, the conventional STGCN model incorporates a static adjacency matrix, which cannot learn to adapt to changes in the connectivity of the sensors. In a dynamic scenario, where spatial relationships change frequently due to the increase in traffic conditions, this becomes a major drawback.

Therefore, several variants of the STGCN model have emerged to learn the dynamic adjacency matrix and incorporate a multi-head spatial attention mechanism with a temporal graph memory [3]–[6]. This allows the model to learn the evolving spatial patterns while identifying the overarching trends in traffic flow.

This study proposes a Spatio-Temporal Graph Convolutional Network (STGCN) for traffic prediction, starting with a baseline implementation and validation. To overcome its limitations, the model is enhanced with dynamic adjacency learning, multi-head spatial attention, and a temporal graph memory network.

The improved model, called Temporal Adaptive Graph Memory STGCN (TAGM-STGCN), better captures spatial and temporal dependencies in traffic data. Its performance is evaluated on large-scale datasets using metrics such as MAE, RMSE, MAPE, classification measures, and efficiency.

II. Literature Review

Traffic prediction plays an important role within ITS, allowing management to control traffic, reduce congestion, and improve mobility within the cities. Traffic prediction studies have been conducted using many different techniques, from simple statistical modeling to more sophisticated deep learning and graph networks. In this section, we discuss previous traffic prediction studies and their motivation.

Time-series models were popular in earlier studies of traffic prediction. ARIMA, one of the earliest methods for predicting freeway traffic using time series, was proposed by Ahmed and Cook [7] and is effective for short-term traffic prediction.

However, the main problem with the use of ARIMA models is that they make linear assumptions about traffic behavior. SVR was first introduced by Wu, Ho, and Lee for modeling the travel times in the road networks using the method of kernel functions [8]. The SVR approach performs more accurately compared to traditional statistical methods; however, although it outperforms them in many cases, it fails to take into account any spatial correlation between multiple road sections. Lv et al. have applied a stacked autoencoder to their deep neural network [9] in order to capture the hierarchical nature of traffic data. Through this, they were able to achieve better prediction results compared to other machine learning approaches. Nonetheless, such methods consider temporal aspects while ignoring the spatial aspect.

Another important innovation in deep learning that can be applied for traffic forecasting involves LSTM (Long Short-Term Memory). Ma et al. utilized LSTMs for forecasting the speed of traffic flow on highways using the data collected by traffic sensors [10]. The strengths of LSTMs include ability to model long-term dependencies in sequential data. As in the case of SAEs, their main emphasis lies on temporal aspects rather than spatial ones.

Given the importance of spatial information in transportation systems, scientists have tried to integrate graph learning techniques with deep learning algorithms [11], [12]. One notable achievement in this regard is the spatio-temporal graph convolutional network (STGCN) proposed by Yu et al [2].. STGCN utilizes graph convolutions in road-segment graphs in order to exploit spatial correlations and couples it with temporal convolutions to achieve superior performance compared to previous approaches.

Li, Yu, Shahabi, and Liu built upon the idea of graph-based learning techniques, and developed the Diffusion Convolutional Recurrent Neural Network (DCRNN) for traffic prediction [3]. DCRNN views traffic flow as a diffusive process on a directed graph and captures the temporal behavior using recurrent neural networks. Their model was effective at identifying and modeling the complex spatial-temporal interactions present in large traffic networks. The use of recurrent networks in their model increases the amount of computation required and thus increases training times for the model.

Graph WaveNet, proposed by Wu et al., is another widely used model for traffic forecasting [4]. It incorporates graph convolution into dilated temporal convolution layers in order to efficiently model long-range temporal dependencies. Graph WaveNet also develops an adaptive adjacency matrix to enable learning graph structures directly from traffic data rather than only depending on previously defined road network connectivity. While the method provides improvements in predictive accuracy, the dynamically learned graph structures may vary dramatically between time-steps, potentially leading to unstable representations in space.

To provide further improvements in the adaptability of graph learning, Bai et al. developed the Adaptive Graph Convolutional Recurrent Network (AGCRN) [6]. AGCRN learns node embeddings in order to create adaptive graph structures for traffic prediction. Learning graph connectivity directly from data allows AGCRN to learn hidden spatial relationships in traffic data that do not exist in pre-defined road network graphs. However, like many other graph learning algorithms, the adaptive graphs created at each time-step will likely be very sensitive to the presence of noise and short-term fluctuations in the traffic data being observed.

More recently, researchers have started exploring ways to implement dynamic graph learning methods. One example of this is the Graph Multi-Attention Network (GMAN), proposed by Zheng et al [5]. The GMAN utilizes multi-attention to capture the spatio-temporal dependency of the traffic data, learning the relation between sensors over time. This allows the flexible learning of traffic behavior, although drastic changes in the graph may induce instability.

While significant improvements have been made in traffic prediction, there are still common drawbacks that most existing traffic prediction models suffer from. They include using a fixed road network graph and neglecting the changing nature of spatial dependency. Others create dynamic graphs of traffic; however, these are often influenced by noise in traffic data and therefore may vary dramatically [4], [6].

A. Research Gap

Although there have been developments in the area of spatiotemporal prediction, most algorithms, such as STGCN, utilize static GSOs without incorporating temporal variation in their spatial dependency assumptions [2]. Dynamic graph-based approaches incorporate time-dependent adjacency matrices but fail to account for the temporal preservation of any structural relationships [4], [6].

Furthermore, current approaches do not take into account traffic regimes, where different convolution kernels can be applied based on the state of traffic.

III. Methodology

In this portion of the paper we describe a new Temporal Adaptive Graph Memory Spatio-Temporal Graph Convolutional Network (TAGM-STGCN) system, which utilizes spatio-temporal graph convolutional networks to forecast the speed of urban traffic. The main features of this system can be broken down into four categories: (i) definitions of problems and representations of input data, (ii) construction of dynamic graphs using multi-head attention, (iii) temporal graph memory with adaptive regime-aware fusion, and (iv) training of the models and ablation studies.

This Fig. 1 illustrates the end-to-end data flow of the TAGM-STGCN model. It demonstrates how raw sensor time-series data is preprocessed and passed through parallel modules, Dynamic Adjacency and Temporal Graph Memory, to capture both instantaneous and long-term spatial-temporal dependencies for final speed prediction. It starts with traffic sensor data, followed by preprocessing and graph construction, including dynamic graph generation. The model then applies dynamic graph learning, multi-head attention, and temporal convolution within the proposed TAGM-STGCN framework

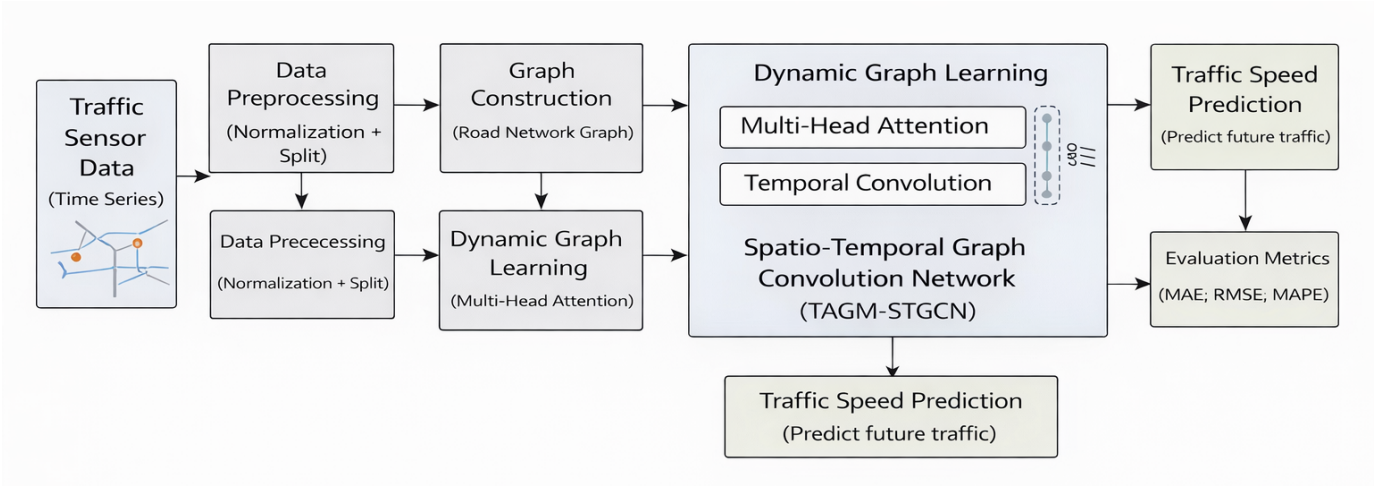

Fig. 1: Conceptual framework of the proposed TAGM-STGCN model.

to capture complex spatial-temporal dependencies. Finally, the system outputs predicted traffic speed, evaluated using performance metrics such as MAE, RMSE, and MAPE.

A. Problem Formulation

Let $G = (V, E, A)$ denote a road network graph, where V represents the set of N sensor nodes, E represents the set of edges corresponding to road segments, and $A \in \mathbb{R}^{N \times N}$ denotes the adjacency matrix encoding spatial connectivity between sensors. Each node $V_i \in V$ records traffic speed observations at each discrete time step. The traffic conditions observed by sensors are represented in a matrix $X \in \mathbb{R}^{T \times N}$, where T is the total number of time steps; each row $X_t \in \mathbb{R}^N$ is the traffic velocity vector at time t that was recorded with the help of all N sensors. Given a historical window of $n_{his} = 12$ consecutive time steps (corresponding to 60 minutes of traffic observations recorded at 5-minute intervals), the model predicts the future traffic speeds for the next $n_{pred} = 12$ time steps. Formally, the forecasting task can be defined as learning a mapping function f such that:

$$f(X_{t-n_{his}+1}, \ldots, X_t; G) \rightarrow X_{T+1}, \ldots, X_{T+n_{pred}}$$

It splits the dataset into a 70/10/20 set for training, validation, and testing. All traffic speed values are normalized using zero-mean unit-variance standardization (StandardScaler). The scaler is fitted on the training data and then applied to the validation and test sets to prevent data leakage.

B. Static Graph Construction

The static graph structure is derived from the physical road network adjacency matrix A, which is loaded from a precomputed sparse matrix for each dataset. To regularize spectral convolution, the raw adjacency matrix is symmetrized and normalized to produce a Graph Shift Operator (GSO). Specifically, the symmetric normalized adjacency is computed as:

$$\tilde{A} = D^{-1/2}(A + I)D^{-1/2}$$

where D denotes the diagonal degree matrix of $(A+I)$, and I represents the identity matrix. The Chebyshev normalization procedure transforms the final obtained graph shift operator by its process of mapping matrix spectral radius values to the interval $[-1, 1]$. The normalization process leads to the establishment of numerical stability in the training process involving the Chebyshev polynomial graph convolution operations.

C. Dynamic Graph Construction via Multi-Head Attention

Traffic patterns change over time, altering spatial relationships between roads. The model addresses this using a Dynamic Adjacency module that learns a unique graph per batch. The input tensor, $X \in \mathbb{R}^{B \times C \times T}$ is first processed to learn the node representations. The features are averagely pooled in the channel dimension and then processed using a channel projection layer and temporal convolution to learn short-term patterns. After temporal aggregation, a node embedding matrix $E \in \mathbb{R}^{B \times N \times H}$ is obtained, representing the recent traffic dynamics of each node. These node embeddings are projected into query (Q) and key (K) representations and used to compute a scaled dot-product attention score:

$$A(h) = \text{Softmax}\left(\frac{Q(h)K(h)^T}{\sqrt{H_{head}}}\right) \tag{1}$$

where h denotes the attention head. The adjacency matrices from the different attention heads are averaged to obtain the dynamic adjacency matrix $A_{dyn} \in \mathbb{R}^{B \times N \times N}$. Most importantly, as the adjacency matrix is computed on each input window separately, the model is able to generate a different graph for each window of time, specializing the feature that unique graphs for every single time frame, enabling the model to capture dynamic changes in the spatial relationships over time.

D. Temporal Adaptive Graph Memory (TAGM)

Dynamic adjacency captures real-time spatial correlations but can be unstable due to noise. To address this, a Temporal

Adaptive Graph Memory (TAGM) module maintains stable historical graph representations using an exponential moving average (EMA):

$$M_t = \mu M_{t-1} + (1-\mu)\bar{A}_t$$

where μ denotes the momentum parameter and $\bar{A}_t$ represents the batch-averaged dynamic adjacency matrix. The graph memory acts as a low-pass filter, preserving long-term spatial patterns while gradually adapting to evolving traffic conditions.

E. Traffic Regime Encoder and Adaptive Graph Fusion

Urban traffic operates under multiple regimes such as free flow, moderate congestion, and heavy congestion. In real-world datasets, approximately 60% of traffic speeds fall within the range of 40–45 km/h, representing moderate traffic flow conditions. To capture such variations, a Regime Encoder is introduced to learn contextual traffic states. The encoder processes the input traffic signals using temporal convolution layers followed by fully connected layers to generate a compact regime embedding. This embedding is used to compute adaptive weights that combine three graph structures: static adjacency A_{static}, dynamic adjacency A_{dyn}, and memory adjacency A_{mem} . The final adjacency matrix is computed as:

$$A_{final} = \alpha A_{static} + \beta A_{dyn} + \gamma A_{mem}$$

where α, β, γ are adaptive weights learned from the regime embedding.

F. Model Training

The proposed model uses Mean Squared Error (MSE) as its loss function which calculates the difference between predicted traffic speed and actual traffic speed. The system uses a graph smoothness regularization term to ensure stable graph learning by measuring changes in dynamic adjacency matrices. The proposed model uses gradient optimization with gradient clipping as its training method to stop gradient explosions. The system uses early stopping methods to protect against overfitting.

G. Evaluation Metrics

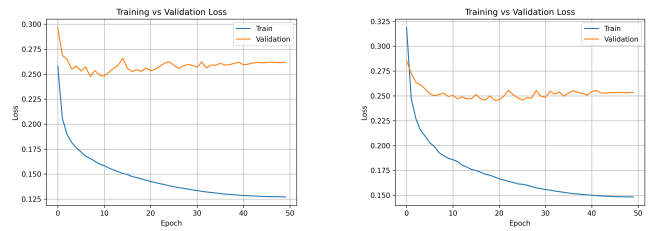
Model performance is evaluated using **MAE, RMSE, and MAPE**, calculated on inverse-transformed traffic speed values.

IV. Experimental Results

Experiments on STGCN models are performed on PeMSD7 and PEMS-BAY datasets with a prediction horizon of 15, 30, and 60 minutes.The performance of the model is analyzed based on MAE, RMSE, MAPE, and classification measures like Accuracy, Precision, Recall, and F1-score.

A. Training Behavior and Convergence

The AdamW optimizer, cosine learning rate scheduling, dropout regularization, and early stopping together improve the stability of the training dynamics and accelerate convergence. These results confirm that the proposed training strategy improves the optimization stability compared to the original STGCN training configuration.



(a) PEMS-BAY (b) PeMSD7-M

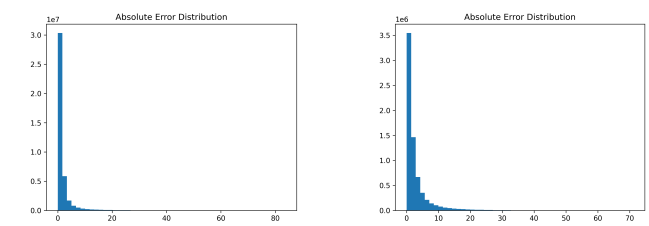
Fig. 2: Training vs. validation loss curves

The results for the PeMSD7 dataset are shown in Fig.2(b).

B. Error Distribution Analysis

The distribution of absolute prediction errors shows that most errors are concentrated near zero. Only a small number of samples exhibit larger prediction errors. The outliers track sudden traffic changes which result from congestion events and unpredictable traffic patterns.

The error distribution demonstrates that the model maintains its accuracy across different traffic conditions which shows its overall strength.The error distributions are illustrated in Fig. 3.



(a) PEMS-BAY (b) PeMSD7-M

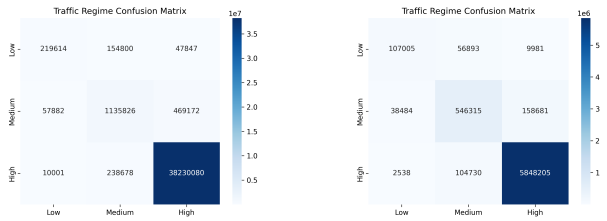
Fig. 3: Absolute error distribution

C. Traffic Regime Classification

The model predicts three different traffic conditions which include Low, Medium, and High Congestion based on the speed of the traffic. The confusion matrix shows that the predictions focus on the diagonal path which leads to high classification accuracy. The system successfully identifies high congestion states which match the actual conditions present in the real-world application.

D. Prediction Behavior

The strong diagonal alignment in these matrices confirms that the model is highly reliable at classifying traffic into Low,

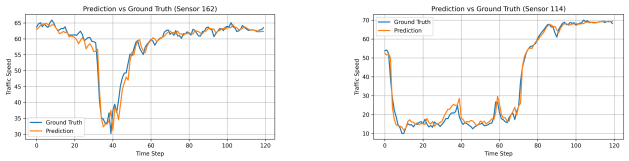


(a) PEMS-BAY (b) PeMSD7-M

Fig. 4: Traffic regime confusion matrices

Medium, and High congestion states. It specifically highlights the model's strength in identifying high-congestion regimes, which is critical for real-world intelligent transportation systems.

The predicted curves match the actual curves for all sensors with tight accuracy. The results demonstrate that the model successfully acquires knowledge about time-based relationships present in traffic patterns.



(a) PEMS-BAY (b) PeMSD7-M

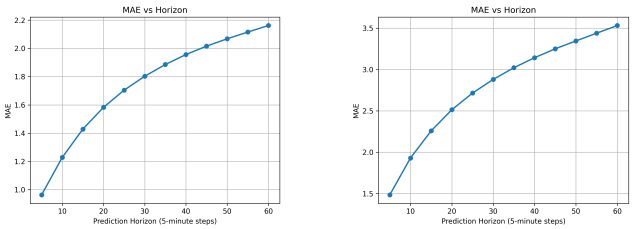
Fig. 5: Prediction vs. ground truth comparison

The prediction results are illustrated in Fig.5(a) and Fig.5(b).

These plots show that the predicted speed curves track the ground truth data with high precision. The model successfully captures both the steady-state free-flow periods and the sharp speed drops that characterize the onset of peak-hour congestion.

E. Multi-Horizon Forecasting Performance

Accuracy is evaluated across multiple horizons; errors rise with longer forecasts but MAE increases steadily, indicating consistent performance. The model effectively captures both short- and long-term traffic trends.



(a) PEMS-BAY (b) PeMSD7-M

Fig. 6: MAE vs. prediction horizon

The multi-horizon forecasting performance is shown in Fig. 6

This analysis shows a gradual, linear increase in error as the forecasting window expands from 15 to 60 minutes. The slow rate of error growth demonstrates the model's robustness and its capability to maintain useful accuracy even for long-term horizons where uncertainty is higher.

V. Model Comparison

The comparison includes conventional methods, i.e., HA, ARIMA, SVR, FNN, as well as the advanced state-of-the-art deep learning techniques such as FC-LSTM, GCGRU, STGCN, Graph WaveNet, STTN, GMAN and METGNN.

A. Results on PeMSD7 Dataset

Findings based on PeMSD7 data set (226 sensors) show that our experiment is successful in replicating the results of Yu et al. (2018).

The models built on the STGCN architecture show better performance than HA, ARIMA, and SVR using measures like MAE and RMSE. The Dynamic Multi-Head STGCN shows the best performance among all models due to multi-head attention and dynamic graph learning.

Another model built on STGCN is the TAGM-STGCN (regime-based fusion+temporal graph memory). The model shows similar performance; differences between the

The performance comparison results for the PeMSD7 dataset are presented in Table I and Table II.

B. Results on PEMS-BAY Dataset

Experiments on the PEMS-BAY dataset (around 325 sensors) validate the proposed approach; the performance of the baseline model aligns with previous work.The dynamic adjacency matrix accounts for changes in traffic conditions, which allows the Dynamic Multi-Head STGCN model to perform marginally better than the baseline in terms of MA The integration of temporal graph memory maintains prediction

accuracy, as evidenced by the TAGM-STGCN model's consistent performance over all prediction horizons. All STGCN-based methods exhibit noticeably lower prediction errors when compared to conventional statistical models.

TAGM-STGCN	0.975	0.825	0.740	0.789

The performance comparison results for the PEMS-BAY dataset are presented in Table III and Table IV.

C. Classification Performance

Classification results for traffic regime classification have good accuracy on all models. The model named Dynamic Multi-Head STGCN gives the best performance (Accuracy: 0.947, F1-score: 0.799), which demonstrates its ability to learn spatial information well.

VI. Conclusion

The proposed model in this paper is called the TAGM-STGCN, an improved version of the standard STGCN, which leverages dynamic graph learning, temporal memory mechanisms, and regime-based graph fusion strategies. Unlike conventional STGCN models with static graphs, the TAGM-STGCN model uses dynamic graphs by applying the temporal memory mechanism to ensure stability during evolving spatial dependence modeling. Experiments show that the performance of the proposed TAGM-STGCN model in predicting traffic flows was effective and efficient using two datasets, which are PeMSD7 and PEMS-BAY. Using the PeMSD7 dataset (with a prediction horizon of 15 minutes), the TAGM-STGCN model obtained an MAE of 2.24, RMSE of 3.89, and MAPE of 5.14. It shows that the proposed model has achieved the same performance level as the conventional STGCN model, which recorded MAE = 2.25, RMSE = 3.90, and MAPE = 5.13. The same result is also observed in PEMS-BAY with MAE = 1.41, RMSE = 2.62, and MAPE = 2.96. As for classification performance, the proposed model recorded an accuracy of 0.945 in PeMSD7 and 0.975 in PEMS-BAY, demonstrating that the model has excellent capabilities of
